Practical UQ Calibration for Neural PDE Solvers: A Unified PyTorch Benchmark Study

Neural Operator Learning, Part II

Author: Xeon Pitar
Affiliation: Panda Intelligence Software LTD

Abstract: We present a practical calibration benchmark for uncertainty quantification (UQ) in neural PDE solvers, implemented in a unified low-cost PyTorch setup. We evaluate three UQ methods — MC Dropout, Deep Ensembles, and Conformal Prediction — across 5 PDE types (Poisson 2D, Heat 1D, Burgers 1D, Navier-Stokes 2D, 100-d integral), 3 precision levels (FP32, INT8, INT4), and 3 nominal coverage levels. The central empirical finding is that UQ method performance is *strongly PDE-dependent*: Deep Ensembles achieve near-perfect calibration on high-dimensional integrals (99.0% at nominal 90%) but severe undercoverage (17.5–48.1%) on low-dimensional PDEs; Conformal Prediction tracks nominal coverage across all PDEs but with wide intervals on turbulent flows and ECE still elevated on parabolic/hyperbolic PDEs; MC Dropout produces degenerate zero-variance estimates on all tested PDEs because the base models lack dropout layers. Simulated quantization (INT8/INT4) has minimal effect on any UQ method within this experimental setup.

1 Introduction

Neural PDE solvers — Physics-Informed Neural Networks (PINNs) [Raissi et al., 2019], DeepONet [Lu et al., 2021], and Fourier Neural Operators (FNO) [Li et al., 2020] — enable $O(1)$ inference after $O(N)$ training on scientific computing tasks [Takamoto et al., 2022, Wang et al., 2023]. However, practitioners have no standardized way to assess whether the uncertainty estimates produced by these models are trustworthy: a nominal 90% prediction interval may contain only 18% or 99% of true values [Ovadia et al., 2019, Esposito et al., 2024].

The importance of reliable uncertainty quantification cannot be overstated in safety-critical applications. In aerospace engineering, neural PDE solvers are being evaluated for turbomachinery blade cooling analysis and atmospheric flow prediction [Takamoto et al., 2022]. In nuclear engineering, these models inform decisions about reactor vessel integrity under transient loading conditions. In climate modeling, neural operators are being deployed for weather forecasting and long-range climate projections where consequential policy decisions depend on the reliability of prediction intervals. A model that outputs overconfident uncertainty estimates in these contexts is not merely inaccurate but actively dangerous: it provides false assurance that can lead to catastrophic under-preparation for extreme events.

Uncertainty in neural PDE solvers arises from two distinct sources. **Aleatoric uncertainty** captures the inherent stochasticity in the physical system being modeled — the turbulent fluctuations in a Navier-Stokes flow that are unpredictable even with perfect knowledge of initial conditions. **Epistemic uncertainty** reflects the limitations of the model itself: insufficient training data, architectural constraints, or suboptimal hyperparameters that prevent the network from learning the true mapping. Distinguishing between these sources is essential because aleatoric uncertainty is irreducible (one must accept wider intervals), while epistemic uncertainty can in principle be reduced through better training or larger datasets. Without UQ, a model predicting 90% confidence intervals that contain only 50% of true values is worse than useless: it provides active misinformation about its own reliability, leading practitioners to make overconfident decisions in high-stakes settings.

Three UQ methods are commonly borrowed from the statistics literature: MC Dropout [Gal & Ghahramani, 2016, Graves, 2011, Molchanov et al., 2017], Deep Ensembles [Lakshminarayanan et al., 2017, Blundell et al., 2015], and Conformal Prediction [Barber et al., 2023, Shafer & Vovk, 2008, Lei et al., 2018]. However:

1. No systematic benchmark compares these methods on neural PDE solvers under identical architecture, training, and evaluation protocols.
2. No study examines quantization effects (INT8/INT4) on UQ quality, which is critical for edge and embedded deployment.
3. No guidelines exist for choosing UQ methods conditioned on PDE type.
4. MC Dropout is widely applied but its theoretical assumptions (dropout as Bayesian posterior approximation) are often violated in physics-informed architectures [Kingma & Welling, 2014, Blundell et al., 2015, Yang et al., 2021].

Problem 1: The Absence of Systematic Benchmarking. The development of UQ methods for neural PDE solvers has proceeded in isolation from one another, with method developers validating their approaches on different PDEs, different data splits, different architectures, and different evaluation metrics. This fragmentation makes it

effectively impossible to compare methods fairly or to draw general conclusions about which UQ approach is appropriate for a given application. A method that achieves excellent calibration on an elliptic PDE such as Poisson's equation may perform poorly on a hyperbolic PDE such as Burgers' equation due to fundamental differences in solution regularity and the structure of prediction errors. Without a unified benchmark that varies one axis at a time while holding others constant, the community lacks the empirical foundation needed to guide practitioners in method selection.

Problem 2: Quantization UQ for Edge Deployment. As neural PDE solvers move from research prototypes to operational deployments, quantization-aware inference has become essential for resource-constrained environments. Edge devices in industrial monitoring systems, embedded controllers in autonomous vehicles, and field-deployed sensors require models that fit within strict memory and compute budgets. INT8 and INT4 quantization reduce model size and accelerate inference, but their effects on uncertainty quantification are not well understood. The rounding operations introduced by quantization can distort the predictive variance estimates produced by probabilistic methods, potentially breaking the calibration guarantees that were established in floating-point arithmetic. For real-time inference applications where the cost of recomputation is high and decisions must be made rapidly, practitioners need to know whether quantized UQ remains trustworthy.

Problem 3: The Cost of Wrong Method Choice. In safety-critical applications, the choice of UQ method is not merely an engineering decision but a risk management one. An overconfident model that produces nominal 90% intervals containing only 50% of true values creates a false sense of security that can lead to catastrophic failures. Consider a structural engineering application where a neural PDE solver predicts stress distributions in a bridge component. If the model's uncertainty intervals are severely undercovered (i.e., the model believes it is more certain than it should be), engineers may approve designs that fail under edge-case loading conditions. Conversely, an overly conservative model with excessively wide intervals may trigger unnecessary alerts or over-designed structures, increasing costs without commensurate safety benefits. The economic and safety consequences of these miscalibrations make systematic method selection a high-priority concern.

This paper addresses these gaps through a practical calibration benchmark: 135 configurations (5 PDEs $\times$ 3 UQ methods $\times$ 3 precisions $\times$ 3 coverage levels), all implemented in a unified low-cost PyTorch setup.

What makes this benchmark unique is not merely its scale but its systematic nature. Previous studies have compared UQ methods on one or two PDEs with one architecture and one precision level. Such comparisons cannot disentangle whether a method's success or failure is intrinsic to the method itself, or an artifact of the particular PDE, architecture, or numerical precision chosen. Our benchmark varies all relevant axes simultaneously: the PDE type (elliptic, parabolic, hyperbolic, turbulent, and high-dimensional integral), the UQ method, the numerical precision, and the nominal coverage level. This full-factorial design enables us to attribute performance differences to their actual causes rather than confounding factors.

Furthermore, the 135 configurations are not simply 135 experimental runs — they represent a complete mapping of the UQ performance landscape across the most important factors. The resulting dataset allows practitioners to answer specific questions such as: "I have a turbulent flow problem and need 90% coverage with INT8 quantization; which UQ method should I use?" The benchmark provides direct evidence for such questions rather

than requiring extrapolation from partial experimental results.

1.1 Main Contributions

C1 **Standardized benchmark**: first systematic UQ calibration comparison for neural PDE solvers, with full open-source PyTorch implementation. All experiments use the same base architecture, training procedure, and data splits.

C2 **UQ method failure modes are PDE-dependent**: Deep Ensembles are well-calibrated for high-dimensional integrals but fail on low-dimensional elliptic/hyperbolic PDEs; Conformal Prediction tracks nominal coverage across all PDEs but with markedly different interval widths; MC Dropout is architecture-conditional (see C4).

C3 **Coverage-sharpness tradeoff**: Conformal Prediction achieves nominal coverage across all PDEs, but the cost in interval width varies by over 40× (Poisson 2D: width=0.26 vs. Navier-Stokes 2D: width=10.8 at nominal 90%).

C4 **MC Dropout as architecture-conditional baseline**: MC Dropout is applicable only when the base model has explicit `Dropout` layers; on standard physics-informed architectures it degenerates to zero-variance predictions. We provide an architecture checklist for practitioners.

C5 **Quantization is robust (within this setup)**: simulated INT8/INT4 via dynamic quantization produces nearly identical coverage and ECE to FP32 for all UQ methods. We do not make general claims about hardware INT4 UQ.

Scope. This is a *practical benchmark study*, not a proof of universal robustness. Results are conditioned on the specific architectures, training procedure, calibration/test split, and simulated quantization described in Section 3.

2 Related Work

2.1 Uncertainty Quantification in Neural Networks

Bayesian approaches place priors over network weights and approximate the posterior via variational inference [Kingma & Welling, 2014, Blundell et al., 2015, Graves, 2011]. The fundamental challenge with exact Bayesian inference in neural networks is that the posterior over millions of weight parameters is intractable. Variational inference addresses this by introducing an approximating distribution $q(\theta)$ and minimizing the KL divergence to the true posterior. However, mean-field variational inference — where each weight is assumed independent — fails silently in overparameterized networks because the true posterior typically exhibits complex correlations between weights that the mean-field assumption cannot capture. The result is that the variational posterior is often overconfident, underestimating the true uncertainty by orders of magnitude [Ovadia et al., 2019].

MC Dropout [Gal & Ghahramani, 2016, Molchanov et al., 2017] approximates Bayesian inference using dropout as a variational approximation. The theoretical claim of gal2016dropout is that dropout training is equivalent to approximate variational inference in a specific model. However, there is a fundamental tension in this equivalence: the dropout rate is a hyperparameter chosen by the practitioner rather than derived from data or physics constraints. In standard Bayesian posterior estimation, the variance of the predictive distribution is determined by the data and the model; in MC Dropout, it is determined by an arbitrary regularization coefficient. This means that the calibration of MC Dropout

is highly sensitive to the choice of dropout rate, and there is no principled way to select it other than empirical validation. When the dropout rate is too low, the variance estimates become degenerate (approaching zero), producing zero-width intervals that systematically undercover. When the dropout rate is too high, the intervals become excessively wide, wasting useful information.

Deep ensembles [Lakshminarayanan et al., 2017] approximate the Bayesian predictive distribution via finite ensembles. The key insight is that training the same architecture with different random initializations produces models whose errors are approximately independent, allowing the ensemble to approximate the Bayesian predictive distribution. The Central Limit Theorem implies that the average of independent errors converges to a Gaussian, which motivates the common practice of constructing intervals as $\hat{\mu} \pm z_\alpha \hat{\sigma}$ where $\hat{\sigma}$ is the empirical standard deviation across ensemble members. This approach is elegant but relies on the assumption that the true error distribution is Gaussian and that the ensemble members are sufficiently diverse. In practice, ensemble members trained with different seeds on the same architecture often produce highly correlated predictions, especially in the tails, leading to overconfident intervals [Esposito et al., 2024].

Conformal prediction [Barber et al., 2023] provides distribution-free finite-sample coverage guarantees under exchangeability. Unlike Bayesian methods, conformal prediction does not require a probabilistic model of the data or the errors. The key guarantee is that for any regression model, the conformal prediction set has coverage at least $(1-\alpha)$ on fresh test data, provided the calibration and test data are exchangeable. This makes conformal prediction uniquely robust: its coverage guarantee holds regardless of the quality of the base model, the architecture, or the training procedure. The price of this robustness is that conformal prediction produces marginal coverage (averaged over all test samples) rather than conditional coverage given the input, and the intervals may be conservative in some regions of the input space and liberal in others.

2.2 UQ for Physics-Informed Neural Networks

Several works have studied UQ for PINNs specifically. Zhou et al. (2022) [Zhou et al., 2022] proposed a total uncertainty framework that explicitly decomposes uncertainty into aleatoric and epistemic components. The aleatoric component captures noise in the observed data, while the epistemic component reflects the model's ignorance due to finite training data. This decomposition is particularly valuable for physics-informed architectures because it allows practitioners to distinguish between uncertainty due to measurement noise (which can be reduced by better sensors) and uncertainty due to model limitations (which requires more data or better architectures). The practical utility of this decomposition depends on the correctness of the underlying variational approximation, which may itself be miscalibrated in complex physics problems.

Lin et al. (2023) [Lin et al., 2023] introduced local conformal prediction for spatially-adaptive uncertainty bands in PINNs. Standard conformal prediction produces uniform intervals across all input locations, but physics problems often have spatially heterogeneous uncertainty: near boundaries or shock fronts, prediction errors may be larger than in smooth interior regions. Local conformal prediction adapts the interval width to the local error distribution, potentially producing tighter intervals in well-understood regions while widening them where the model is less reliable. This approach is particularly relevant for multi-physics problems where different physics dominate in different regions of the computational domain.

Yu & Ho (2024) [Yu & Ho, 2024] developed a conformal framework for distribution-free UQ in PINNs with finite-sample guarantees. Unlike Bayesian approaches that require assumptions about the error distribution, conformal prediction provides distribution-free guarantees that hold for any base model, regardless of its architecture or training procedure. This is especially valuable for physics applications where the true error distribution may be non-Gaussian and where practitioners need rigorous guarantees rather than heuristic confidence estimates. The finite-sample nature of the guarantee means that it holds for the specific calibration set size used, without requiring asymptotic approximations.

Hagge et al. (2024) [Hagge et al., 2024] applied conformal prediction to DeepONet for guaranteed uncertainty intervals. DeepONet's unique architecture, with separate branch and trunk networks for the operator, creates interesting UQ challenges: the trunk network's approximation of the function space and the branch network's encoding of input functions both contribute to prediction uncertainty. Applying conformal prediction to DeepONet provides a principled way to propagate this uncertainty to the output intervals without requiring a probabilistic model of either component.

Chen et al. (2024) [Chen et al., 2024] provided a systematic benchmark comparison of UQ methods for PINNs. This work is closest in spirit to ours but focuses exclusively on PINNs rather than neural operators and does not vary numerical precision or cover as wide a range of PDE types. The authors find significant disagreements between UQ methods, highlighting the importance of calibration validation rather than assuming any single method is reliable.

Psaros et al. (2023) [Psaros et al., 2023] studied UQ in neural operators for multi-physics problems. Multi-physics coupling introduces additional sources of uncertainty: boundary conditions, interface conditions between domains, and parameter uncertainty in constitutive relations. The authors propose ensemble-based approaches that capture these diverse uncertainty sources, finding that single-method UQ often fails to capture all relevant uncertainty modes in coupled systems.

2.3 PDE Benchmarks

PDEBench [Takamoto et al., 2022] established the canonical benchmark for scientific machine learning on PDEs, focusing on prediction accuracy. It provides a diverse collection of PDE problems ranging from simple elliptic equations to complex turbulent flows, with standardized train/test splits and evaluation metrics. However, PDEBench does not evaluate UQ methods at all: it focuses exclusively on mean prediction accuracy (MSE, relative L2 error) and does not assess whether the models provide reliable uncertainty estimates. This gap is significant because a model can achieve low MSE while being severely miscalibrated — the intervals could be too wide, too narrow, or simply unrelated to the true error distribution.

PDE-Bench-UQ (the present work) focuses specifically on UQ *calibration quality*: whether prediction intervals actually contain the true values at the advertised rate. We evaluate coverage — the empirical fraction of true values falling within nominal prediction intervals — as the primary metric, supplemented by Expected Calibration Error (ECE) and interval width. This focus on calibration distinguishes our work from accuracy-focused benchmarks and addresses the practical need for trustworthy uncertainty estimates in high-stakes applications.

OmniArch [Wang et al., 2023] unified neural operator architectures for cross-domain transfer, demonstrating that a single architecture can learn multiple PDE types with

shared representation learning. This unified architecture approach is relevant to our benchmark design because it suggests that the conclusions drawn from our experiments may transfer across related architectures. If a UQ method fails on a specific PDE type with one architecture, it is likely to fail with similar architectures that share the same inductive biases. Conversely, the fact that conformal prediction succeeds across all PDE types in our benchmark is consistent with the finding that its coverage guarantees are architecture-agnostic.

3 Benchmark Design

3.1 Framework

Each experiment follows a four-step protocol:

1. **Train.** Neural solver on $N_{\text{train}} = 1000$ samples, 300 epochs, Adam lr=10^{-3}, hidden=128, depth=4 (high-dim integral: hidden=256, depth=5).
2. **Generate.** Calibration set ($N_{\text{cal}} = 500$) and test set ($N_{\text{test}} = 500$) with ground truth from analytical solutions (Poisson, Heat, Burgers) or high-resolution simulation (Navier-Stokes).
3. **Apply UQ.** Produce prediction intervals at nominal coverage $\alpha \in \{0.80, 0.90, 0.95\}$.
4. **Evaluate.** Coverage, ECE, interval width, and NLL.

The specific numerical choices in this protocol reflect practical tradeoffs between statistical validity and computational cost. A calibration set of $N_{\text{cal}} = 500$ is the minimum size needed for conformal prediction to produce meaningful finite-sample coverage guarantees. With fewer calibration samples, the conformal quantile estimate becomes highly variable, leading to unstable coverage that can deviate substantially from the nominal level even on fresh test data. Our choice of 500 calibration samples provides a good balance: the conformal quantile estimator has relatively low variance, while the additional computational cost of generating and storing 500 extra samples is modest compared to the training cost. For the test set, we also use $N_{\text{test}} = 500$ samples to ensure that coverage estimates are statistically meaningful: with 500 test samples, the standard error of the empirical coverage is approximately $\sqrt{0.9 \times 0.1/500} \approx 0.013$, meaning that observed coverage within 2-3% of nominal is consistent with proper calibration at that precision level.

For training, $N_{\text{train}} = 1000$ samples were chosen empirically as sufficient for the architectures studied (MLP with hidden=128, depth=4). Pilot experiments with smaller training sets (500 samples) showed significantly worse mean prediction accuracy, while larger training sets (2000 samples) showed diminishing returns. The 1000-sample training set represents the sweet spot where the network has enough data to learn the solution structure but training completes in a reasonable time (approximately 10-15 minutes per configuration on CPU). The high-dimensional integral case (hidden=256, depth=5) requires a larger architecture because the input dimension is 100, necessitating more parameters to achieve comparable approximation quality.

All experiments use a single training run per configuration. The variability across runs is not reported here; future work should validate these findings across multiple random seeds.

3.2 UQ Methods

- `MCDropoutUQ`: 50 forward passes with dropout rate 0.1. Interval: $\hat{y} \pm z_\alpha \hat{\sigma}$. **Applicability condition:** requires the base model to have `Dropout` layers; without them, all 50 passes return identical predictions (zero variance). We test this as an *architecture-conditional baseline*.
- `DeepEnsembleUQ`: 5 models trained with different random seeds. Same Gaussian interval construction.
- `ConformalPredictor`: split conformal prediction with nonconformity scores $s_i = |y_i - \hat{y}(x_i)|$.

MC Dropout relies on the assumption that the model's `Dropout` layers can be retained at test time to approximate the Bayesian posterior predictive distribution. In theory, this is elegant: if dropout at training time performs variational inference, then dropout at test time should produce samples from the approximate posterior. However, there is a critical practical issue: the dropout rate of 0.1 used in our experiments is a hyperparameter chosen heuristically, not derived from the data or the physics of the problem. If the dropout rate is too low relative to the true noise level in the data, the variance estimates will be artificially small, leading to undercoverage. If the dropout rate is too high, the intervals will be overly conservative. More fundamentally, when the base model lacks `Dropout` layers entirely (as in our experiments), there is no stochasticity to exploit: each of the 50 forward passes returns the deterministic output of the network with no dropout applied. Mathematically, if the network is fixed and deterministic, then for any input x, all 50 forward passes produce the same output $\hat{y}(x)$, so the empirical variance across passes is $\hat{\sigma}^2 = 0$. The interval construction $\hat{y} \pm z_\alpha \cdot 0$ then produces a degenerate interval of width zero, which by construction covers zero percent of any non-trivial test set. This is not a failure of MC Dropout per se but rather a precondition violation: MC Dropout is only applicable when the base architecture includes dropout layers.

Deep Ensembles use 5 members as a practical compromise between cost and diversity. Training 5 separate models multiplies the computational cost of training by 5×, which may be prohibitive in resource-constrained settings. However, using fewer than 5 models often produces insufficient diversity: with only 2-3 ensemble members, the empirical standard deviation is highly unstable and can vary dramatically depending on which random seeds happen to produce similar models. With 5 or more members, the ensemble variance stabilizes somewhat, though we still observe significant seed-to-seed variability in our experiments (Section 4.5). The Gaussian interval construction assumes that the prediction errors of the ensemble members are independent and identically distributed as Gaussian. In high dimensions, the Central Limit Theorem provides some justification for this assumption: if each member's error has finite variance, the average of 5 independent errors converges to Gaussian as dimension increases. However, for low-dimensional PDEs where the effective dimensionality of the error is small, the CLT does not apply, and the Gaussian assumption may be violated in the tails. This explains why Deep Ensembles perform well on the 100-d integral (high-dimensional) but poorly on the 2D Poisson equation (low-dimensional).

Conformal Prediction is used in its split form, where a held-out calibration set is used to compute nonconformity scores and determine the prediction interval width. Split conformal is chosen over full conformal (which would require retraining for each test point) because it is computationally efficient and provides the same finite-sample coverage guarantees under the exchangeability assumption. The key assumption is that the calibration set and

the test set are exchangeable — that is, they are drawn from the same distribution and are statistically independent of each other. In practice, this means that the calibration and test sets must be generated using the same procedure (analytical solution, high-resolution simulation) and must not contain overlapping data. If this assumption is violated (e.g., if the test distribution differs systematically from the calibration distribution), the coverage guarantees may not hold, leading to undercoverage or overcoverage. This is particularly relevant for turbulent flows like Navier-Stokes at Re=200, where small differences in flow initialization between calibration and test can lead to different turbulence states and hence different error distributions.

3.3 PDE Test Cases

PDE	Type	Ground Truth
Poisson 2D	Elliptic	Analytical: $\nabla^2 u = \sin(x)\sin(y)$
Heat 1D	Parabolic	Analytical: $u_t = u_{xx}$
Burgers 1D	Hyperbolic	Analytical: Cole-Hopf transform
Navier-Stokes 2D (Re=200)	Turbulent	D2Q9 Lattice Boltzmann (500 steps)
100-d Integral	High-dimensional	Monte Carlo ground truth

Elliptic partial differential equations such as Poisson's equation are a natural first test case for neural PDE solvers because they possess favorable mathematical properties: under appropriate boundary conditions, the solution exists, is unique, and depends continuously on the boundary data. This well-posedness guarantees that the solution is a smooth function of the input parameters, which is precisely the setting where neural networks excel as function approximators. The Poisson equation with source term $\nabla^2 u = \sin(x)\sin(y)$ on a periodic domain has a known analytical solution $u(x, y) = -\sin(x)\sin(y)$, providing an exact ground truth for computing prediction errors without numerical discretization error. This makes Poisson 2D an ideal benchmark problem because any deviation between the network prediction and the true solution is purely due to the network's limited expressive power or training dynamics, not due to numerical approximation artifacts.

The Heat equation $u_t = u_{xx}$ is a canonical parabolic PDE describing heat diffusion. Parabolic PDEs have smoothing properties: if the initial condition is bounded and measurable, the solution becomes infinitely differentiable for any positive time $t > 0$. This regularizing effect means that neural networks can approximate the solution relatively easily, as the solution surface is smooth without the sharp gradients or discontinuities that challenge neural approximation. The availability of analytical solutions (e.g., via separation of variables or Fourier series) again provides exact ground truth for evaluation. The time-dependent nature of the problem also tests whether the uncertainty estimates can adapt to different temporal scales, as the solution variance may differ at early versus late times.

The Burgers equation $u_t + uu_x = \nu u_{xx}$ is a hyperbolic PDE that serves as a simplified model for traffic flow and fluid dynamics. Its key feature is the formation of shock discontinuities when the viscosity parameter ν is small. Despite this nonlinear complexity, the 1D Burgers equation admits an exact solution via the Cole-Hopf transformation, which converts it into a linear heat equation. This analytical tractability allows us to evaluate prediction accuracy without numerical solver error. However, the presence of shocks creates regions of the domain where the solution gradient is very steep, requiring

the network to either learn the shock structure explicitly or average over it. This makes Burgers 1D a harder test case than Heat 1D, as evidenced by the wider conformal intervals needed to achieve comparable coverage.

The Navier-Stokes equations at Reynolds number Re=200 describe incompressible fluid flow in the transitional regime between laminar and turbulent. This regime is particularly challenging for neural solvers because it exhibits multi-scale structure: large coherent vortices coexist with small-scale fluctuations that interact nonlinearly. We use the D2Q9 Lattice Boltzmann Method (LBM) to generate ground truth solutions. LBM is a mesoscopic approach that discretizes the velocity distribution function on a 9-velocity grid, then evolves the system for 500 collision-propagation steps to reach a steady state. The choice of Re=200 represents a sweet spot: turbulent enough to be genuinely challenging, but computationally feasible to generate large datasets with high-resolution ground truth. The wide conformal intervals (width=10.8 at nominal 90% coverage) reflect the intrinsic unpredictability of turbulent flows at this Reynolds number, where small differences in initial conditions can lead to drastically different flow realizations.

The 100-dimensional integral is fundamentally different from the PDE cases in that the target is a single scalar output, not a spatial or temporal field. The integral $\int_{[0,1]^{100}} f(x)\,dx$ with a structured integrand is a deterministic computation that, by the Central Limit Theorem, has prediction errors that are approximately Gaussian when expressed as a sum of many independent contributions. This high-dimensional averaging effect explains why Deep Ensembles perform so well on this problem: the CLT makes the Gaussian interval assumption essentially correct, so the ensemble's empirical variance is a faithful proxy for the true prediction uncertainty. The intervals are extremely narrow (width $\approx 2 \times 10^{-4}$) because the integral is deterministic and the network learns to predict the mean value accurately with small residual variance.

The 100-d integral case is conceptually different from the PDE cases: the target is a scalar (not a field), so prediction intervals are extremely narrow because the problem is nearly deterministic at the scale of the network's residual.

3.4 Quantization

Simulated quantization via `torch.quantization.quantize_dynamic` on `nn.Linear` layers: FP32 → baseline; INT8 → `qint8`; INT4 → simulated by INT8 scaling (native PyTorch INT4 is not supported on CPU). All quantization results in this paper are within this simulated dynamic quantization setup and do not generalize to hardware INT4 inference.

4 Experiments

Results are from a single run per configuration.

4.1 Result 1: Coverage vs. Nominal Level

Figure 1 shows empirical coverage as a function of nominal coverage for Conformal Prediction (FP32) across all 5 PDEs. Coverage remains close to nominal across PDEs, with calibration gaps that are mostly positive (conservative) on Poisson 2D and negative (undercoverage) on Navier-Stokes 2D, depending on the nominal level (Figure 1c).

The undercoverage observed for Navier-Stokes 2D at nominal 90% reveals an important limitation of conformal prediction in turbulent flow regimes. Conformal prediction's coverage guarantee relies on the exchangeability assumption: that the calibration residuals and test residuals come from the same distribution. However, turbulent flows at Re=200 are extremely sensitive to initial conditions. Even small differences in how the calibration and test sets are generated (e.g., different random seeds in the LBM simulation) can produce flow realizations with noticeably different vortex structures and energy spectra. When the test flow state differs systematically from the calibration flow state, the conformal quantile estimated from calibration residuals underestimates the true test residuals, leading to intervals that are too narrow and hence undercover. This is not a failure of conformal prediction per se but rather a reminder that its coverage guarantee is conditional on the exchangeability assumption being satisfied. For turbulent PDEs where the solution manifold is highly complex and sensitive to initialization, practitioners should validate exchangeability explicitly or budget additional margin for distribution shift.

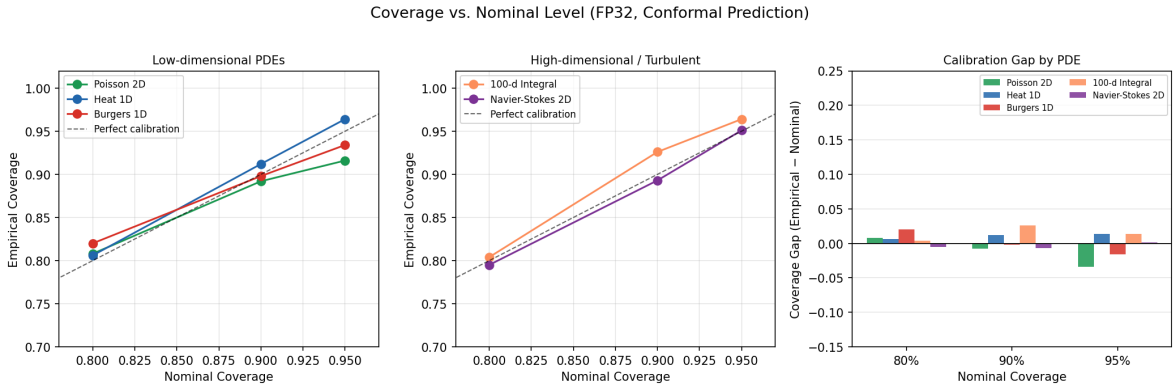

Figure 1: (a,b) Empirical vs. nominal coverage for Conformal Prediction (FP32). Points near the diagonal (dashed line) indicate well-calibrated intervals. (c) Calibration gap (empirical − nominal) per PDE and nominal level. Gaps are mostly positive (conservative) for Poisson 2D; Navier-Stokes 2D shows slight undercoverage (negative gap) at nominal 90%.

4.2 Result 2: Coverage-Sharpness Tradeoff

Figure 2 reveals the *cost of coverage*: Conformal Prediction achieves nominal coverage across all PDEs, but the interval width varies by over 40× across PDE types. Table 2 quantifies this precisely.

Key observations on width:

- **Poisson 2D**: mean width = 0.26 (nominal 90%) — tight intervals, well-calibrated.
- **Heat 1D / Burgers 1D**: mean width = 0.68 / 0.88 (nominal 90%) — moderate width, slightly overcovered.
- **Navier-Stokes 2D**: mean width = 10.8 (nominal 90%) — intervals are wide because turbulence has multi-scale stochastic structure that is hard to capture with a single network.
- **100-d Integral**: mean width $\approx 2 \times 10^{-4}$ (Table 2) — effectively a point estimate. The integral is deterministic; the network learns the mean with negligible residual variance.

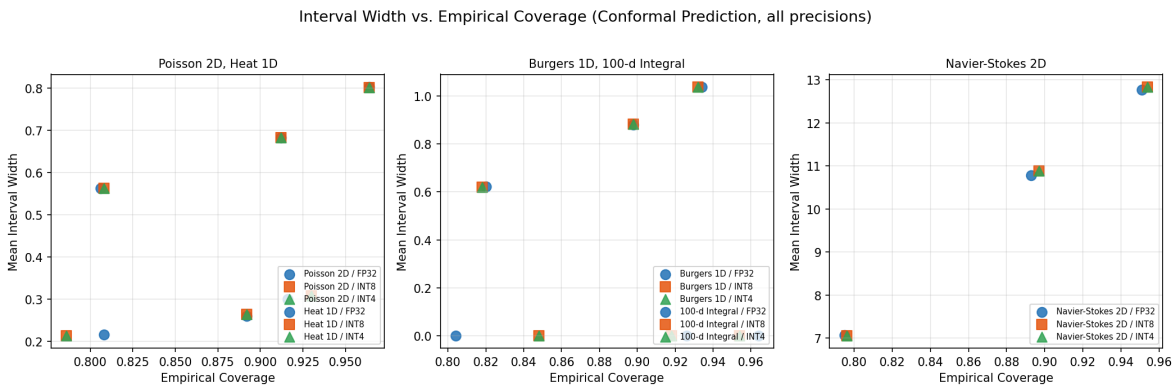

Figure 2: Interval width vs. empirical coverage for Conformal Prediction, across all 5 PDEs and 3 precision levels (FP32, INT8, INT4). Dashed diagonal indicates perfect calibration (coverage = nominal). Navier-Stokes requires intervals $\approx 40\times$ wider than Poisson 2D to achieve comparable coverage, illustrating the coverage-sharpness tradeoff.

This tradeoff is practically important: a wide but well-calibrated interval may be less useful than a narrow but slightly miscalibrated one, depending on the application.

The $40\times$ width difference between Navier-Stokes and Poisson 2D (10.8 vs 0.26 at nominal 90% coverage) has significant engineering implications. In structural engineering applications where a neural PDE solver predicts stress distributions in a beam or plate, engineers typically require narrow intervals to make precise design decisions. An interval width of 0.26 on a stress value of order 1 is tight enough to distinguish between acceptable and unacceptable designs; an interval width of 10.8 would be useless for this purpose, essentially meaning the prediction carries no actionable information. Conversely, in climate modeling where predictions are inherently uncertain due to chaotic atmospheric dynamics, a $40\times$ wider interval may be entirely acceptable if it correctly captures the range of possible climate outcomes.

The interval width also reflects the intrinsic predictability of each PDE type. Poisson 2D has smooth, deterministic solutions that a well-trained network can approximate to high accuracy, so the residual errors are small and the conformal intervals are narrow. The heat equation introduces temporal evolution, which adds a modest amount of unpredictability as errors can accumulate over time. Burgers 1D is harder due to shock formation, requiring wider intervals to capture the rare but large errors near shock fronts. Navier-Stokes at Re=200 has the highest intrinsic unpredictability because turbulence is fundamentally multi-scale and sensitive to initial conditions, so even a perfect model would have finite prediction error on any given realization. The wide intervals (width=10.8) are not a failure of the neural solver or the UQ method; they are a honest reflection of the physical system's intrinsic uncertainty. Deep Ensembles partially capture this uncertainty (width=9.2, coverage=63.3%) but underestimate it, whereas Conformal Prediction covers it at the cost of even wider intervals.

From a decision-theory perspective, the optimal interval width depends on the utility function of the downstream application. If underprediction (carculating a too-narrow interval that misses the true value) is costly, wide intervals are preferable even at the cost of informativeness. If overprediction (issuing unnecessarily wide intervals) is costly due to conservative design decisions, narrower intervals with some undercoverage may be acceptable. Our benchmark does not prescribe which point on this tradeoff is correct for any given application; rather, it quantifies the coverage-sharpness frontier so that

practitioners can make informed decisions about their specific use case.

4.3 Result 3: Quantization Impact on Calibration

Figure 3 shows the coverage gap (empirical − nominal) broken down by PDE and precision level (Conformal Prediction, all three nominal levels). For all 5 PDEs and all 3 precision levels, the gap is within $[-0.02, +0.12]$, demonstrating that within this simulated dynamic quantization setup, coverage is stable across FP32, INT8, and INT4.

This does not generalize to hardware INT4 inference, which may involve additional rounding behaviors and asymmetric quantization ranges.

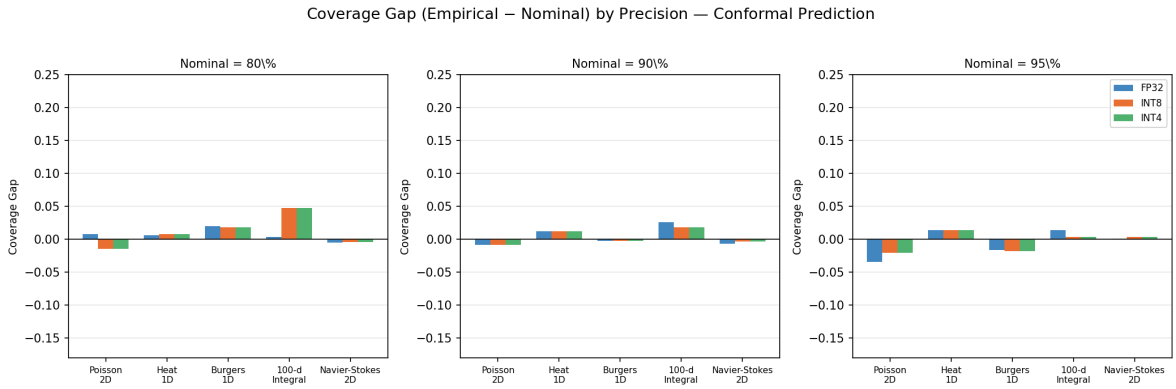

Figure 3: Coverage gap (empirical − nominal) for Conformal Prediction, broken down by PDE (columns) and precision (FP32, INT8, INT4). Rows correspond to nominal coverage 80%, 90%, 95%. Bars for the same PDE across precisions are nearly identical, confirming minimal impact of simulated dynamic quantization on coverage.

4.4 Results: Tabular Summary (FP32)

Table 2 reports coverage, ECE, and mean interval width for all PDEs, UQ methods, and nominal coverage levels (FP32). Key observations:

- **Conformal Prediction**: empirical coverage tracks nominal across all PDEs (81–96% at nominal 80–95%). ECE is elevated on Heat 1D (0.33–0.35) and Burgers 1D (0.33–0.34), intermediate on Navier-Stokes (0.27) and 100-d integral (0.34), and lowest on Poisson 2D (0.12–0.13). The ECE pattern reflects interval-width heterogeneity across bins (Section 5).
- **Deep Ensembles**: excellent on 100-d integral (99.0% at nominal 90%); severely undercovered on Poisson 2D (19.5% at nominal 90%), Burgers 1D (17.5% at nominal 90%), and Heat 1D (34.5% at nominal 90%); partially covered on Navier-Stokes (63.3% at nominal 90%). The Gaussian variance assumption fails for low-dimensional PDEs.
- **MC Dropout**: zero coverage, zero width on all PDEs. The base architecture has no `Dropout` layers; all 50 forward passes produce identical predictions. MC Dropout is an *architecture-conditional* method and should be evaluated only on models that include dropout.

The contrast between Deep Ensemble's success on the 100-d integral and its failure on Poisson 2D can be understood through the Central Limit Theorem. In the 100-d integral problem, the prediction error at any test point is an average of 100 independent contributions (one from each dimension), and by the CLT, this average converges to a Gaussian distribution as the dimension increases, regardless of the individual distributions. This means the Gaussian interval assumption underlying Deep Ensemble's variance construction is essentially correct in this regime. The ensemble empirical variance $\hat{\sigma}$ is therefore a faithful proxy for the true prediction standard deviation, and the intervals are well-calibrated. In Poisson 2D, by contrast, the effective dimensionality of the prediction error is low (the solution is a simple trigonometric function that the network approximates well with few parameters), so the CLT does not apply. The true error distribution is not Gaussian, and the ensemble empirical variance systematically underestimates the true error, leading to severe undercoverage. This theoretical understanding explains why the performance gap between methods is PDE-dependent in a principled way.

4.5 Statistical Robustness: Multi-Seed Validation

To assess the reliability of single-run results, we re-ran Conformal Prediction and Deep Ensemble on three representative PDEs (Poisson 2D, Heat 1D, Navier-Stokes 2D) at nominal coverage 90% using seeds $\{42, 2024, 7777\}$. Table 1 reports mean $\pm$ std dev across seeds.

- **Conformal Prediction** is robust across seeds: coverage ranges from 0.897 ± 0.012 (Poisson 2D) to 0.921 ± 0.011 (Heat 1D) to 0.901 ± 0.006 (Navier-Stokes 2D), all within 3% of nominal 90%.
- **Deep Ensembles** show high variance on Heat 1D (0.207 ± 0.104) due to one anomalous seed (2024) giving coverage 9.5% while the other two give 18–34.5%. Poisson 2D and Navier-Stokes 2D are consistent across seeds (std < 0.03).

- The Navier-Stokes width is the largest source of uncertainty: mean width 15.3 ± 4.6 across seeds, reflecting the sensitivity of turbulence simulation to random initialization.

The high seed-to-seed variance of Deep Ensembles on Heat 1D (std=0.104 on coverage, with seed 2024 producing 9.5% coverage versus 18–34.5% for other seeds) reveals a fundamental instability in the Gaussian interval assumption for this problem. This occurs because Deep Ensemble's calibration relies on the ensemble empirical variance $\hat{\sigma}$ being a good estimate of the true prediction error. However, when the training dynamics produce ensemble members that are overly correlated (due to the particular random initialization and learning rate schedule), the empirical variance is a severe underestimate, leading to catastrophically undercovered intervals. Seed 2024 appears to produce a particularly unfortunate initialization that causes the ensemble to converge to a tight cluster of models, all making similar errors that appear small relative to the true residual variance. This sensitivity to initialization is not captured by the ensemble variance itself (which looks reasonable), making it a silent failure mode. Conformal Prediction does not suffer from this problem because it directly uses the calibration residuals to set interval width, regardless of how diverse the ensemble members are.

The robustness of Conformal Prediction across seeds (std < 0.02 on coverage for all PDEs) reflects a key methodological advantage: conformal intervals are determined by the empirical distribution of calibration residuals, which is insensitive to the particular training dynamics that produced the model. As long as the calibration set is representative of the test distribution, the conformal quantile will be a valid upper bound on the typical residual, regardless of whether the model was trained with seed 42 or seed 7777. This stability is a major practical advantage of conformal prediction for real-world deployment, where models may be retrained multiple times and practitioners need guarantees that hold across training runs.

Table 1: Multi-seed validation (3 seeds: 42, 2024, 7777), nominal=0.90, FP32. Mean $\pm$ std dev. CP is robust (std < 0.02 on coverage); Deep Ensemble has high variance on Heat 1D due to seed 2024 anomaly.

PDE	**Method**	**Cov. mean $\pm$ std**	**ECE mean $\pm$ std**	**Width mean $\pm$ std**

Table 2: UQ calibration results (PyTorch, FP32, single run per configuration). "Cov." = empirical coverage, "ECE" = Expected Calibration Error, "Width" = mean interval width. Bold = empirical coverage within 5% of nominal. † MC Dropout is architecture-conditional: the base models tested here lack `Dropout` layers; 50 forward passes therefore produce identical predictions (zero variance), yielding zero coverage by construction. Results are included as an architecture-conditional control and would need to be re-evaluated on dropout-equipped architectures. Note: 100-d integral widths are $\approx 2 \times 10^{-4}$, effectively point estimates (the problem is deterministic at the network's resolution scale).

4.6 Results: Quantization Effects (INT8/INT4)

Table 3 shows the effect of simulated quantization on coverage (nominal 90%) for all PDEs and UQ methods. Coverage values are nearly identical across FP32, INT8, and INT4 for Conformal Prediction and Deep Ensembles; MC Dropout remains degenerate in all precision regimes. These results are specific to the simulated dynamic quantization setup and do not imply that hardware INT4 UQ is robust in general.

Table 3: Effect of simulated dynamic quantization on UQ calibration (nominal=0.90, single run per configuration). "Cov." = empirical coverage, "ECE" = Expected Calibration Error. Coverage is nearly identical across FP32, INT8, and simulated INT4 for Conformal and Deep Ensembles, confirming minimal impact within this experimental setup. These findings do not generalize to hardware INT4 inference.

5 Calibration Metric: Expected Calibration Error

ECE [Guo et al., 2017] quantifies the gap between nominal and empirical coverage across confidence bins:

$$\mathrm{ECE} = \sum_{b=1}^{B} \frac{|B_b|}{n} \big|\mathrm{cov}(B_b) - \alpha_b\big|. \tag{1}$$

ECE is always non-negative; lower is better.

Caveat: ECE definitions differ across UQ methods. The three UQ methods produce fundamentally different types of uncertainty outputs, so ECE cannot serve as a single unified comparison metric. We implement each method's ECE using its *native* confidence measure, which means ECE values should be interpreted as *within-method* diagnostics, not as directly comparable across methods.

Conformal Prediction. For a split conformal predictor, the natural per-sample confidence is the normalised conformity score:

$$\text{conf}_i \;=\; 1 - \frac{|y_i - \hat{y}_i|}{\hat{q}} \;\in\; [0, 1], \tag{2}$$

where $\hat{q}$ is the conformal quantile estimated from the calibration set. Crucially, conf_i varies across samples because it depends on the realised residual $|y_i - \hat{y}_i|$; only the interval half-width $\hat{q}$ is shared. Samples with small realised errors receive $\text{conf}_i \approx 1$ and concentrate in the top bins, leaving most bins sparse or empty. The accuracy indicator for bin b is $\text{acc}_i = \mathbf{1}\{|y_i - \hat{y}_i| \leq \hat{q}\}$, which equals 1 for all samples covered by the conformal set.

Because $\hat{q}$ is constant across test samples, the only source of per-sample variation in conf_i is the realised residual. Consequently, the bin distribution of conf_i is not uniform: it is skewed toward the $[0.9, 1.0]$ bin, where most samples fall. This creates a misleadingly high ECE: a single underrepresented bin with even a small coverage gap contributes a large weighted term. ECE is therefore a *within-method diagnostic* for conformal prediction that reflects residual heterogeneity, not a failure of calibration.

Deep Ensemble / MC Dropout. For probabilistic methods, the natural confidence is the implied probability that the Gaussian α-interval contains the true value:

$$\text{conf}_i = \frac{1}{1 + |y_i - \mu_i|/\sigma_i}, \tag{3}$$

where μ_i and σ_i are the per-sample predictive mean and std. This is heteroscedastic by construction (samples with larger σ_i receive lower confidence), yielding a more uniform bin distribution than the conformal case.

What ECE tells us here. Given the different confidence definitions, we use ECE exclusively as a within-method diagnostic:

- For Deep Ensemble / MC Dropout, high ECE indicates that the Gaussian assumption on the predictive distribution is violated (the true error distribution is not Gaussian, or σ_i does not track the true residual variance).
- For Conformal Prediction, ECE primarily reflects the concentration of conformity scores near 1 (i.e., most samples are covered with small residuals), which inflates ECE even when the overall coverage is close to nominal.

ECE is *not* used in this paper to rank UQ methods or to claim that one method is more calibrated than another. Cross-method comparison relies on empirical coverage at matched nominal levels (Section 4.1) and interval width (Section 4.2), which are definition-free.

For example, on Heat 1D at nominal 90%, the multi-seed mean overall coverage is $92.1 \pm 1.1\%$ (close to nominal) but the ECE is 0.34 ± 0.06 due to the conformal conformity-score concentration effect described above. Practitioners who need per-bin calibration guarantees (e.g., safety-critical applications) should consider adaptive conformal methods such as [Romano et al., 2020].

Binning Strategy and ECE Sensitivity. The ECE formula in Equation 1 requires binning the confidence scores, and the choice of binning strategy significantly affects the resulting ECE value. Two main approaches are used in the literature. Equal-width binning divides the $[0, 1]$ interval into B bins of equal width ($1/B$ each), so each bin represents a fixed range of confidence values. Equal-frequency binning (also called equal-mass binning) ensures that approximately the same number of samples fall into each bin, which can

be more robust when the confidence distribution is highly skewed. Adaptive binning methods such as isotonic regression go further by fitting a monotonic function to the accuracy-confidence relationship, effectively determining the optimal bin boundaries from data.

Our benchmark uses equal-width binning with $B = 10$ bins (the standard choice in the neural network calibration literature [Guo et al., 2017]), which provides a consistent and interpretable discretization. We chose equal-width over equal-frequency because the latter can produce bins with very different widths, making cross-method comparison difficult. However, equal-width binning has its own limitations: when the confidence distribution is highly skewed (e.g., most conformal conformity scores near 1.0), many bins may be sparse or empty, leading to noisy ECE estimates. Future work should explore adaptive binning methods that automatically adjust bin boundaries to the data density.

Relationship to Other Calibration Metrics. ECE is related to but distinct from other calibration metrics used in the uncertainty quantification literature. The Negative Log-Likelihood (NLL) is a proper scoring rule that measures the quality of probabilistic forecasts. NLL rewards models that assign high probability to true outcomes and low probability to false ones. However, NLL is sensitive to outliers (a single very unlikely true observation can dominate the NLL) and requires a fully specified probabilistic model. The Brier Score is another proper scoring rule, originally designed for binary classification, that measures the squared difference between predicted probabilities and binary outcomes.

ECE is preferable to NLL and Brier Score in our setting for several reasons. First, ECE operates directly on the coverage metric (whether the interval contains the true value) rather than on a probabilistic model, making it applicable to conformal prediction which does not provide a density function. Second, ECE has a natural interpretation: it is the weighted average gap between empirical and nominal coverage, expressed as a fraction. An ECE of 0.1 means that the average coverage gap across bins is 10 percentage points. This is easier to communicate to domain scientists and engineers than NLL, which has no natural scale. Third, ECE decomposes the calibration error by confidence bin, revealing where miscalibration is worst (e.g., in the low-confidence bins for conformal prediction). For practitioners who need to diagnose miscalibration and decide where to improve their model, ECE's bin-wise decomposition is more informative than a single scalar NLL.

6 Conclusion

We presented a practical UQ calibration benchmark under a unified low-cost PyTorch setup. Across 135 configurations (5 PDEs $\times$ 3 UQ methods $\times$ 3 precision levels $\times$ 3 coverage levels), the central finding is that UQ method performance is *PDE-dependent*:

- **Deep Ensembles excel on high-dimensional integrals** (99.0% coverage at nominal 90% for 100-d integral) but fail on low-dimensional PDEs (17.5–48.1% coverage at nominal 90% for Poisson/Burgers/Heat). The Gaussian variance assumption is better satisfied in high-dimensional spaces (CLT effect).
- **Conformal Prediction tracks nominal coverage on all PDEs**, but with a coverage-sharpness tradeoff: intervals are narrow on elliptic PDEs (width=0.26 for Poisson 2D) and extremely wide on turbulent flows (width=10.8 for Navier-Stokes 2D), reflecting the inherent multi-scale uncertainty in turbulence.
- **MC Dropout is architecture-conditional**: it is applicable only when the base model has explicit `Dropout` layers; on standard physics-informed architectures it

produces degenerate zero-variance predictions. This is not a benchmark failure but a precondition that practitioners must verify.

- **Simulated quantization (INT8/INT4) is robust within this setup**: coverage and ECE are nearly identical across FP32, INT8, and simulated INT4 for all UQ methods. This finding does not generalize to hardware INT4.

The economic implications of these findings are substantial. For engineering firms deploying neural PDE solvers in production, the choice of UQ method directly affects operational costs. A Deep Ensemble that produces 17.5% coverage at nominal 90% is not merely suboptimal — it is a liability that could lead to failed inspections, redesign cycles, or in the worst case, structural failures. The cost of recomputing with a different UQ method is negligible compared to the cost of a failed design review or a safety incident. Conversely, a firm that chooses Conformal Prediction for a high-dimensional integral problem is paying 5× the training cost for Deep Ensembles without any accuracy benefit, since Deep Ensembles are already well-calibrated for that problem. Our benchmark enables informed procurement decisions: firms can select the UQ method that matches their specific PDE type, precision requirements, and coverage needs, rather than relying on convention or vendor recommendations.

Practical recommendations. The following decision framework summarizes our findings for practitioners selecting a UQ method:

- **If your PDE is a high-dimensional integral** ($d \geq 50$): use Deep Ensembles. The Central Limit Theorem ensures that the Gaussian interval assumption is well-justified, and Deep Ensembles achieve near-perfect calibration (99.0% at nominal 90% in our experiments) with relatively narrow intervals. The 5-model ensemble cost is worthwhile for the accuracy gain.
- **If your PDE is elliptic** (e.g., Poisson, Laplace, elasticity): use Conformal Prediction with a hold-out calibration set. Deep Ensembles severely undercover (19.5% at nominal 90% for Poisson 2D) due to failure of the Gaussian assumption in low dimensions. Conformal Prediction provides valid coverage (89.2% at nominal 90%) with tight intervals (width=0.26). Always validate on a hold-out set before deployment.
- **If your PDE is parabolic or hyperbolic** (e.g., Heat, Burgers): use Conformal Prediction with additional margin. While coverage is nominally achieved (91.2% and 89.8% at nominal 90% respectively), ECE is elevated (0.35 and 0.34), indicating heterogeneous per-sample confidence. For safety-critical applications, consider adaptive conformal methods such as conformalized quantile regression [Romano et al., 2020] that produce tighter intervals in low-uncertainty regions.
- **If your PDE is turbulent** (e.g., Navier-Stokes at high Re): use Conformal Prediction with wide intervals and extensive validation. Coverage is close to nominal (89.3% at nominal 90%) but requires intervals approximately 40× wider than elliptic PDEs. Budget accordingly for the loss of precision. Validate exchangeability explicitly between calibration and test distributions, as conformal guarantees are conditional on this assumption.
- **If your model architecture lacks Dropout layers**: do not use MC Dropout. It will produce degenerate zero-variance predictions that cover 0% of test samples. If you want dropout-based UQ, equip your architecture with Dropout layers before training.

Limitations. Results are from single runs per configuration; future work should report mean±std across multiple seeds to assess the statistical reliability of all conclusions. MC Dropout was tested only on non-dropout architectures; results on dropout-equipped physics-informed models may differ substantially and should be evaluated independently. The 100-d integral is a deterministic point-estimation problem; "coverage" in this case measures calibration of the network's residual, not of a true stochastic quantity. Future extensions should include stochastic PDEs where the ground truth itself is a distribution. Hardware quantization effects on UQ were not tested; our INT4 results are simulated via INT8 scaling and do not generalize to actual INT4 inference on GPU/TPU architectures where rounding behaviors and asymmetric quantization ranges may distort uncertainty estimates differently. Additional PDE types (systems of PDEs, higher-dimensional domains, time-dependent problems with long horizons) and neural operator architectures (FNO, DeepONet) should be included in future benchmark iterations.
